THE REAL BENEFITS OF THE PAS 4-QUADRANT LINEAR POWER AMPLIFIERS INTEGRATED IN PHIL – *POWER HARDWARE IN THE LOOP*

The real time simulation of complex systems is commonly known using simulator systems from companies like RTDS or OPAL-RT.

With these systems it is possible to set up and model the behavior of real existing electrical systems in a virtual world. The virtual world can be connected with the real world using digital and analog interfaces. These interfaces are mostly a set of output and input terminals for the interaction of the simulation and the real world.

If only signal lines are connected to the external real devices (like sensors and actors) the subsystem is called HIL – Hardware-in-the-loop.

Power-Hardware-in-the-loop (PHIL) simulation means the connection of a physical power device like a power amplifier to a virtual simulation system.

Two big subjects are defining the quality and accuracy of a PHIL system:

- 1. The **delay time** between interface output terminal and power output plug of the power amplifer
- 2. The **stability** of the system
 - the stability of the control loop (interaction between simulation and hardware)
 - the electrical stability of the power amplifier's output signal

THE DELAY TIME

The time difference between the output terminal of the PHIL interface and the relating reaction at the output of the power device is defined as the system's delay time.

Actual PHIL simulation systems have delay times between 200µs and 3000µs.

Ultra high speed digital connections are able to decrease the delay time down to 15μ s range for digital powerless I/O terminals.

With a connected power device typical minimum delay times are in the range of 700μ s standard down to 200μ s improved systems.

With the **PAS amplifier** system from Spitzenberger & Spies it is possible to decrease the delay time down to a minimum value of **30µs with AC coupling** and **below 10µs with DC coupling**. With these extra low delay times it is easy to improve the speed of the PHIL system on the power part of the devices up to a factor of 10 in comparison to other systems on the market.

THE STABILITY OF THE OVERALL SYSTEM

Two areas of stability of a PHIL system need to be considered:

On the one hand the regulation loop stability, the interaction between the simulator's output terminals and the feedback of the connected hardware to the simulator's input terminals. On the other hand the speed of the changing of the output signal of the connected power source and it's stability during supplying a connected EUT.

PHIL regulation loop

With the very low transition delay time of the PAS amplifier, the combination of a high level simulator with the technical advanced 4-quadrant power amplifiers from Spitzenberger & Spies will lead to the perfect PHIL testing system.

The lower the time delay between the adjustment of the simulator output parameters and the feedback of measurement data into the simulator is, the better is the stability of the overall PHIL system.

In addition, the system performance increases extensively and the simulation approaches the reality very closely.

THE STABILITY OF THE POWER AMPLIFIER OUTPUT SIGNAL PIES

The power amplifier's output signal stability is depending on the signal rise time, accuracy and the stability of the power source itself. When using standard power sources on the market the stability of the output signal is often limited to real loads.

Fast changes of the output signal must be carried out slowly to avoid overshooting and instability of conventional power amplifier systems

With the **PAS** amplifier system the **power output is always a fast and stable signal** even with high non-linear loads, no matter whether they are pure inductive or pure capacitive.

Any type of PHIL EUT's can be connected. Especially motor-driven components with high initial current consumption can easily be supplied by the PAS. The **short-time power capability of the PAS** can supply the connected motor with the double nominal power for a time period up to 10 minutes.

Even EUT'S with a capacitive input stage like rectifying bridges with high peak current consumption can be supplied using the peak power capability of the PAS. The **PAS peak power capability** extends the output power up to 4 times the nominal power for a time period of up to 3ms.
